Abstract Duchenne muscular dystrophy results from loss of the protein dystrophin, which links the intracellular cytoskeletal network with the extracellular matrix, but deficiency in this function does not fully explain the onset or progression of the disease. While some intracellular events involved in the degeneration of dystrophin-deficient muscle fibers have been well characterized, changes in their secretory profile are undescribed. To analyze the secretome profile of mdx myotubes independently of myonecrosis, we labeled the proteins of mdx and wild-type myotubes with stable isotope-labeled amino acids (SILAC), finding marked enrichment of vesicular markers in the mdx secretome. These included the lysosomal-associated membrane protein, LAMP1, that co-localized in vesicles with an over-secreted cytoskeletal protein, myosin light chain 1.

These LAMP1/MLC1-3-positive vesicles accumulated in the cytosol of mdx myotubes and were secreted into the culture medium in a range of abnormal densities. Restitution of dystrophin expression, by exon skipping, to some 30 % of the control value, partially normalized the secretome profile and the excess LAMP1 accumulation. Together, our results suggest that a lack of dystrophin leads to a general dysregulation of vesicle trafficking. We hypothesize that disturbance of the export of proteins through vesicles occurs before, and then concurrently with, the myonecrotic cascade and contributes chronically to the pathophysiology of DMD, thereby presenting us with a range of new potential therapeutic targets.

MLC1-3	Myosin light chain 1 and 3
PARP1	Poly ADP-ribose polymerase 1
SILAC	Stable isotope labeling with amino acids in cell culture

Introduction

Duchenne muscular dystrophy arises from mutations in the dystrophin gene that prevent synthesis of dystrophin, a structural protein that links intracellular γ -actin to a transmembrane-glycoprotein complex [1, 2]. Its absence weakens the connection of the contractile machinery to the overlying basement membrane [3] disturbing mechanical transmission of myofibril contractions and rendering the

sarcolemma subject to structural disruption as seen by electron microscopy [4] and indicated by the greater penetration of non-cell permeable dyes into muscle fibers of mdx mice subjected to vigorous exercise [5, 6]. Likewise, albumin and immunoglobulins enter skeletal muscle fibers while soluble myofiber proteins such as creatine kinase leak from the muscle fibers into the plasma [7, 8]. In addition, anomalies of calcium handling, arising from dysregulation of ion channels, have been reported in dystrophin-deficient myofibers ([9–11], see [12] for review). High levels of calcium are postulated to contribute to myofiber degeneration and necrosis by activating calcium-dependant proteolysis pathways such as ubiquitous calpains [13, 14]. These recurrent myonecrotic events generate both a regenerative response by the satellite cells and an inflammatory response, the latter gradually assuming a dominant effect as manifest by a progressive replacement of the myofibers by fibrotic and adipose tissue [7]. This failure of regeneration is exacerbated by a progressive attenuation of satellite cell proliferation [15]. According to this model, recurrent myonecrosis is the primary upstream pathological trigger that drives the cumulative and irreversible down-stream pathology.

Although the intracellular events involved in the degeneration of dystrophin-deficient myotubes have been well characterized, the factors secreted by myotubes are unknown. During the last few years, several studies have established the secretory profile of C2C12 myotubes during differentiation [16, 17]. Secreted proteins included growth factors (e.g., follistatin like protein 1, IGF2, TGF), cytokines, and inhibitors of collagenase (e.g., TIMP2). Other secreted factors such as IL-6 [18] and myostatin [19] have been identified to originate from skeletal muscle *in vivo*, implicating it as an endocrine organ. The objective of the present study was to characterize the secretome profile of dystrophin-deficient myotubes as a phenomenon independent of myonecrosis. Comparing wild-type (WT) with dystrophin-deficient (mdx) myotubes, we found that mdx myotubes secreted twice as much total protein and, intriguingly, that most of the secreted proteins are cytoplasmic and not in classical secreted categories. Cluster-based protein functional analysis showed a preponderance of secreted proteins related to vesicles and vesicle trafficking. In further exploration of this, we found that lysosomal-associated membrane protein 1 (LAMP1)-positive vesicles containing myosin light chains 1-3 (MLC1-3; cytoskeletal proteins over-secreted by mdx myotubes in our study) were accumulated in the cytosol and in the secreted products of mdx myotubes. The restitution of dystrophin expression to some 30 % of the control value partially reversed the secretome profiles and decreased the accumulation of LAMP1 vesicles. Together, our results demonstrate that dystrophin deficiency causes dysregulation of vesicle trafficking leading to excess protein secretion distinct from that arising from the catastrophic breakdown

of intracellular regulation seen in myonecrotic lesions *in vivo*. This hypothesis is consistent with investigations of the pre-myonecrotic 16-day-old mdx mouse that reveal atrophic myofibers containing cytosolic accumulations of LAMP1 and high serum concentrations of MLC1-3, supporting the idea of aberrant vesicle secretion and metabolic disturbance as part of a pre-pathogenic process *in vivo*.

Materials and methods

Immortalized myogenic cell clone extraction and maintenance

To study a pure myogenic cell population, we choose to use clonal immortalized H-2K myoblasts extracted as previously described [20] from male H-2K^b-ts58 (CBA/ca X C57Bl/10ScSn) and mdx-H-2K^b-ts58 (CBA/ca X C57Bl/10ScSn-mdx) mice at 1 month of age. This strategy provides reproducible standard cultures that differentiate reliably into myotubes over a period of 2–3 days and avoids contamination by non-muscle cells that can occur with primary cultures. Dystrophin expression was detected by Western blot in WT H-2K myotubes differentiated for 8 days.

Secretome analysis

Proliferation and differentiation media were prepared as previously described [20], containing “labeled D-MEM”, with 4.5 g l⁻¹ glucose, with L-glutamine, without L-arginine, without L-lysine, without sodium pyruvate, without sodium bicarbonate (GIBCO) supplemented with 3.7 g l⁻¹ sodium bicarbonate (Sigma-Aldrich, St. Louis, MO, USA), 0.11 g l⁻¹ sodium pyruvate (Sigma-Aldrich), 0.084 g l⁻¹ ¹³C₆-labeled L-arginine-HCl (Cambridge Isotope Laboratories, Andover, MA, USA), 0.146 g l⁻¹ ¹⁵N₂, ¹³C₆-labeled L-lysine-2HCL (Cambridge Isotope)] or, alternatively, “unlabeled D-MEM” [D-MEM (GIBCO) supplemented as above but with unlabeled rather than labeled L-arginine-HCl (Sigma-Aldrich), and L-lysine-HCl (Sigma-Aldrich).

Dystrophin-null and dystrophin-expressing cell lines were plated at 250,000 cells per 150-cm² flask coated with 0.4 % gelatin (flasks were prepared in triplicate for each condition and cell line), and cultured in labeled or unlabeled proliferation medium for 5 days, then switched to their respective labeled and unlabeled differentiation media for 5 days. The myotubes were washed three times in D-PBS, and three times in D-MEM, and fresh serum-free labeled and unlabeled D-MEM (conditioned media) was added. After 24-h incubation (day 6 of differentiation), the culture media were harvested and centrifuged at 300 × g for 10 min. Supernatant was then centrifuged at 2,000 × g for 20 min 4 °C. Subsequent supernatant was then filtered with

a 22- μ m syringe filter, concentrated as previously described [21] and stored at -80°C . All samples were then loaded on Novex 4–20 % Tris–Glycine Midi Gel (Invitrogen, Carlsbad, CA, USA), electrophoresed at 125 V with Tris–Glycine SDS Buffer (Bio-Rad, Hercules, CA, USA) for 105 min at RT, as previously described [21]. From 48 to 50 bands were excised from fixed gels from each lane, and peptides were extracted as previously described [21] and analyzed by LC–MS/MS.

Liquid chromatography-tandem mass spectrometry

LC–MS/MS was performed on a nano-HPLC system (NanoLC 2D, Eksigent, Dublin, CA) connected to a hybrid LTQ/Orbitrap instrument (Thermo Fisher Scientific, San Jose, CA, USA). Eluting peptides were introduced into the mass spectrometer via a 10-mm silica tip (New Objective Inc., Ringoes, NJ, USA) adapted to a nano-electrospray source (Thermo Fisher Scientific Inc, Waltham, MA, USA). The spray voltage was set at 1.3 kV and the heated capillary at 180°C . The LTQ/Orbitrap was operated in data-dependent mode in which one cycle of experiments consisted of one full-MS survey followed by three sequential pairs of intercalated MS/MS experiments. The targeted ion counts in the ion trap during full-MS, and MS/MS were 30,000 and 10,000, respectively. MS measurements were performed with the Orbitrap at a resolution of 60,000 and accuracy better than 5 ppm. Peptides were fragmented in the linear ion trap using collision-induced dissociation with the collision gas (helium) pressure set at 1.3 mTorr and the normalized collision energy value set at 35 %.

Database search and quantification

Protein identification was performed using Bioworks 3.3 software package equipped with Sequest search engine against *Mus Musculus* SwissProt database (UniProtKB/Swiss-Prot release 15.4 of June 2009) indexed with assumptions for fully enzymatic tryptic cleavage with two missed cleavages and the following possible protein modifications: 16-Da shift for oxidized Met and 6- and 8-Da shifts for stable isotope-labeled Arg and Lys, respectively. The search result was filtered with DTASelect using the following acceptance criteria: DeltaCn (DCn) >0.08 , a variable threshold of Xcorr vs. charge state ($Xcorr \geq 1.8$ for $z = 1$, $Xcorr \geq 2.5$ for $z = 2$, and $Xcorr \geq 3.5$ for $z = 3$, and $Xcorr \geq 4.5$ for $z = 4$). MS spectra for each identified peptide were extracted from raw data using Raw_Xtractor. Census (Yates Lab), proteomic quantification software, was used to generate an extracted ion chromatogram (XIC) for each peptide and measure protein ratios in SILAC-labeled versus unlabeled samples. Data were checked for validity by spectral visualization [22].

Cell culture to assess the amount of protein secreted, cell death, and DNA amount in myotubes

Approximately 500,000 cells of each cell line were plated in 10-cm² Petri dishes coated with 0.4 % gelatin, and cultured in differentiation medium for 5 days. The myotubes were washed three times in D-PBS, and then fresh differentiation medium or conditioned media was added ($n = 5$ per cell line and per condition). For a positive control of apoptosis, two extra Petri dishes were cultured for 12 h with $10 \mu\text{g ml}^{-1}$ camptothecin (Sigma-Aldrich). At day 6 of differentiation, the culture media were harvested, aliquoted, and stored at -80°C for subsequent analysis. The myotubes were scraped into 50 μl of chilled cell lysis buffer (provided with the caspase 9 colorimetric Protease Assay; Invitrogen), incubated on ice for 10 min, and centrifuged at $10,000 \times g$ for 1 min. The supernatants were collected and stored at -80°C for caspase 9 enzyme activity measurements and Western-blot analysis. The pellets were kept at -80°C for DNA extraction.

Assessment of myotube secreted protein quantity, protein and DNA cell content, and caspase 9 activity

The protein concentrations of myotube samples were spectrophotometrically measured at 570 nm using the BCA Protein assay kit (Pierce Biotechnology, Rockford, IL, USA), and the protein amount secreted into the conditioned media was measured using the Coomassie Plus Protein Assay kit (Pierce Biotechnology). DNA was extracted with the DNeasy Blood and Tissue kit (Qiagen, Hilden, Germany), and quantified using a Nanodrop ND-1000 Spectrophotometer. An amount of 50 μg of protein was used to assess the caspase 9 enzyme activity as described by the manufacturer, using the colorimetric Protease Assay from Invitrogen.

Fusion Index, counts of nuclei at different time points of differentiation, and RNA staining

In 24-well plates coated with 0.4 % of gelatin, 50,000 WT and mdx H-2K cells were plated per well and directly cultured in differentiation medium.

Fusion index. Cells were fixed in 4 % formaldehyde (Sigma-Aldrich) for 10 min at 37°C at day 6 of differentiation, ($n = 5$ wells per cell line) washed, stained with $1 \mu\text{g ml}^{-1}$ DAPI (Roche, Mannheim, Germany) for 2 min at room temperature (RT), and washed three times in Dulbecco's PBS (D-PBS, Sigma-Aldrich). A drop of Gel/Mount (Biomedica Crystal Mount) was added to each well to avoid fading. Ten non-overlapping images per well were acquired in a line along the diameter of the well with a Zeiss Axiovert 200 M (Zeiss) and an LD A-Plan 20x/0.30 Ph1 objective (Zeiss) equipped with an AxioCam MR camera (Zeiss). Images were acquired using transmitted-light

differential interference contrast (DIC) optics and a DAPI filter. In each field, the total number of nuclei and the number of nuclei outside myotubes were counted using ImageJ 1.37v (NIH image). The fusion index was then calculated for each well as follows:

$$\text{Fusion index} = \frac{\text{number of nuclei inside mvotubes}}{\text{Total number of nuclei}} \times 100$$

RNA staining and quantification. Myotubes were fixed at day 6 of differentiation ($n = 3/\text{cell line}$), and permeabilized for 10 min at RT in buffer I (20 mM citrate–phosphate, pH 3.0, 0.1 mM EDTA, 0.2 M sucrose, 0.1 % Triton X-100). A negative control was created in an extra well for each cell line by adding RNase A (Puregene) at 0.2 mg ml^{-1} for 1 h at 37°C in buffer I. Then buffer II containing acridine orange (10 mM citrate–phosphate, pH 3.8, 0.1 M NaCl, $20 \mu\text{g ml}^{-1}$ acridine orange) was added to all wells. After 10 min of incubation at RT in the dark, myotubes were washed once in D-PBS, and a drop of Gel/Mount was added to each well. Ten images per well were acquired as described above. The red fluorescence for RNA was acquired using a TRITC-filter, 60-ms exposure. Nuclei were visualized using a GFP filter. The fluorescence intensity was measured in each field using ImageJ 1.37v (NIH image), cumulated for each well, and normalized to the number of nuclei.

Quantification of myofiber F-actin content

Myofibers were isolated from perinatal (1–2 weeks old) WT and mdx mice as described previously [23] and their F-actin content was quantified using the PhAct method [24].

Comparison of nuclear loss when myotubes are cultured in medium with or without serum

Fifty thousand WT and mdx H-2K cells were plated as described in the fusion index section. At day 5 of differentiation, the myotubes were washed three times with D-PBS and cultured in differentiation medium or conditioned media ($n = 5$ per cell lines and per cell conditions) for 24 h, fixed, stained for DAPI, and mounted as described above. Five pictures per well were acquired along the diameter of the well using a Zeiss Axiovert 200 M, with a plan-Neofluor 10x/0.30 objective equipped with an AxioCam MR camera. The total number of nuclei were counted in each field using ImageJ 1.37v (NIH image), and cumulated for each well.

Bioinformatic functional analysis of secreted protein function

All proteins observed with a consistent ratio in both experiments, forward and reversed labeling, were imported into DAVID functional annotation software developed by Huang

et al. [25, 26] based on their UNIPROT accession numbers. Automatic annotation performed by DAVID database was manually revised to ensure accurate assignment. A total of ten subcellular localizations were identified. To have a better understanding of the pathways involved, we used the clustering algorithm proposed by DAVID Database (v 6.7) with high clustering stringency (initial and final group membership: 5; similarity term overlap: 3; multiple linkage threshold 0.5; similarity threshold: 0.85). This identified several functional annotation clusters with a fisher exact p value $< 3.7 \cdot 10^{-2}$, and an enrichment score above 2 (geometric mean in log scale of member's p values: significance being considered at 1.5), see [25, 26] for more details.

Membrane leakage

Fifty thousand WT and mdx H-2K cells were plated as described in the nuclear loss section and directly cultured for 5 days in differentiation medium. The myotubes were then washed three times in D-PBS, and fresh differentiation medium or conditioned media was added, and cells were cultured for a further 24 h. At day 6, $200 \mu\text{g ml}^{-1}$ of dextran 3-kDa Texas red lysine fixable (Invitrogen), $200 \mu\text{g ml}^{-1}$ of dextran 10-kDa Rhodamine green lysine fixable (Invitrogen), $200 \mu\text{g ml}^{-1}$ of dextran 40-kDa Texas red neutral (Invitrogen), or $200 \mu\text{g ml}^{-1}$ of dextran 10-kDa FITC (Invitrogen) were added to each well, and cells were incubated for 5 or 20 min ($n = 2$ per cell line, per condition, and per time point). Cells were gently washed with D-PBS, and the ones that were incubated with dextran 3 and 10 kDa were fixed in 4 % formaldehyde for 10 min at 37°C then washed with D-PBS. A drop of Gel/Mount was added to each well to avoid fading. Cells that were incubated with dextran 10 and 40 kDa were kept in conditioned media or differentiation medium, and analyzed immediately. Five pictures per well were acquired along the diameter of the well using microscopy settings as described in the nuclear loss section. Images were acquired using DIC optics for cell morphology, FITC filter to visualize the dextran 10 kDa (855 ms exposure), and TRITC filter for the dextran 3 and 40 kDa (310-ms exposure). Triton $\times 100$ (0.2 %) was added with the dextran mixtures for the positive controls.

Exon skipping using antisense PMO to rescue dystrophin expression in mdx myotubes

Antisense phosphorodiamidate morpholino (PMO) sequences designed to target exon 23 as previously described [27] were purchased from Gene Tools, LLC, Philomath, OR, USA. Cultures of conditionally immortalized mdx myoblasts were transferred to non-permissive conditions to begin generation of myotubes and $10 \mu\text{M}$ of antisense PMO Ex23 or standard PMO control with a transfection

agent, Endo-Porter (6 μ M; Gene Tools) were added to the medium. After 72-h incubation with the PMO, the medium was changed to a fresh culture medium free of PMOs. At day 5 of differentiation, the myotubes were rinsed and treated as described in the paragraph above for secretome analysis.

Immunoblotting

A total of 2 μ l of mouse plasma or 20 μ g of protein from myotubes were mixed with 4 \times NuPage LDS buffer (Invitrogen) supplemented with 50 mM DTT, heated for 2 min at 85 $^{\circ}$ C, loaded on Novex 4–20 % Tris–Glycine Midi Gel (Invitrogen), and electrophoresed at 125 V with Tris Glycine SDS Buffer (Bio-Rad) for 105 min at RT. Separated proteins were transferred at 400 mA for 1 h at RT onto PVDF membranes (Millipore, Bedford, MA, USA) using Trans-blot SD semi-dry Transfer Cell (Bio-Rad), and thick blotting paper soaked in transfer buffer [Tris glycine Buffer (Bio-Rad) and 20 % methanol (Sigma-Aldrich)]. To check the expression of dystrophin, 40 μ g of protein from myotubes was mixed with 4 \times NuPage LDS buffer as described above, and loaded on Novex 3–8 % Tris–Acetate Midi Gel (Invitrogen), and electrophoresed at 150 V with Tris–Acetate SDS running buffer (Invitrogen) for 70 min at RT. Proteins were then transferred at 45 V overnight at 4 $^{\circ}$ C onto PVDF membranes as described above using transfer buffer with no methanol.

Membranes were blocked in TBS-T (20 mM Tris, 500 mM NaCl, pH = 7.5, 0.1 % Tween 20) supplemented with 5 % non-fat dry milk (Bio-Rad) for 1 h at RT. The gels were stained with Bio-Safe Coomassie (Bio-Rad) for 1 h at RT and de-stained with de-ionized H₂O for 1 h. Membranes were incubated overnight at 4 $^{\circ}$ C with cleaved poly ADP-ribose polymerase (PARP) antibody (1:1,000 in TBS-T-2.5 % milk, Asp214, Cell Signaling), or for 1 h at RT for MLC1-3, dystrophin primaries antibodies [1:200 (monoclonal F310 developed by DSHB, monoclonal DYS1 sold by Novocastra (Leica Biosystems), respectively)]. Membranes were washed three times for 10 min in TBS-T, incubated with immunopure donkey anti-rabbit IgG (Thermo scientific) or with sheep anti-mouse IgG H + L (GE Healthcare) conjugated to horseradish peroxidase (HRP, 1:10,000 in TBS-T 2.5 % milk) or with rabbit anti-mouse IgG2a HRP (1:2,000 in TBS-T 2.5 % milk, Invitrogen) for 1 h at RT, and revealed with Pierce ECL Western Blotting Substrate (Pierce Biotechnology). The films (CL-XPosure Film, Pierce Biotechnology) and the gels were scanned and quantified using ImageJ 1.37v (NIH image).

Vesicle extraction and characterization by electron microscopy

Six millions cells were plated into five flasks and cultured for 5 days in differentiation medium. At day 5, the cells were washed three times with D-PBS and three times with

D-MEM, and cultured for 24 h in 12 ml of conditioned media. The conditioned media from each flask was harvested at day 6, and vesicles of a range of densities were prepared by ultracentrifugation on a sucrose gradient as described previously [28]. Whole-mount secreted membrane vesicles were processed as described in Théry et al. [28]. Observations were made using a CM120 transmission electron microscope (Philips, Eindhoven, The Netherlands) at 80 kV. Images were recorded with a Morada digital camera (Olympus Soft Imaging Solutions GmbH, Münster, Germany) and measures were taken with the associated iTEM software.

LAMP1 quantification and colocalization with MLC-1

Fifty thousand mdx and WT cells were plated on Ibidi slides (Ibidi®) and cultured in differentiation medium for 6 days. Ibidi slides were fixed as described above in the fusion index section, permeabilized, blocked, and immunostained as described in the immunostaining section. Images were acquired under a 63 \times objective on a Zeiss Axiovert 200 M equipped with an AxioCam MR camera, and FITC, TRITC, and DAPI filters. For LAMP1 quantification, cells were stained with rabbit anti-LAMP1 (dilution 1:300, H-228, Santa Cruz Biotechnology (Santa Cruz, CA, USA) and goat anti-rabbit Alexa Fluor 488 (dilution 1:500, Invitrogen). Twenty images were gathered for each slide ($n = 3$). In each field, the total number of nuclei, and the integrated densities of FITC signal over a background threshold of 51 were quantified using ImageJ 1.37v (NIH image). For LAMP1 and MLC-1 co-localization, cells were transfected at day 5 with a fluorescently tagged LAMP1 encoding cDNA using a BacMam System with 60 particles per cell (cell light reagent LAMP1 RFP, Invitrogen) and MLC1 immunostaining was performed using a mouse anti-MLC1 (1:300, S21, DSHB) and goat anti-mouse Alexa Fluor 488 (dilution 1:500, Invitrogen).

Lysosomal activity

Fifty thousand mdx and WT cells were plated on Ibidi slides (Ibidi®) and cultured in differentiation medium for 6 days. The cells were incubated for 1 h with 1 μ M of LysoSensor Yellow/Blue DND-160 (Invitrogen). Images were acquired under a 63 \times objective as described above. The FITC and DAPI signals per myotubes were quantified using ImageJ 1.37v (NIH image).

Immunostaining

Tibialis anterior and *Extensor digitorum longus* from C57Bl10-mdx and C57Bl10 aged 16 days were harvested ($n = 4$), frozen in liquid-nitrogen-cooled isopentane and stored at -80° C. Transverse sections were cut on a cryostat microtome at

–20 °C, and incubated for 1 h at RT in permeabilization and blocking buffer [TBS-T, 0.05 % Triton ×100, 2 % BSA 2 % (w:v), 20 % Goat serum]. Primary antibodies were diluted in permeabilization and blocking buffer overnight at RT [laminin a-2 (clone 4H8-2, 1:400, Axxora), LAMP1 (dilution 1:300, H-228, Santa Cruz Biotechnology)]. The slides were washed three times in TBS-T 10 min at RT. Secondary antibodies were diluted in permeabilization and blocking buffer [goat anti-rat Alexa Fluor 488 (1:400, Invitrogen), donkey anti-rabbit Alexa Fluor 595 (1:400, Invitrogen)]. The slides were washed three times in TBS-T 10 min at RT, counter-stained with 1 µg ml⁻¹ DAPI for 2 min, rinsed two times, and mounted with Gel/Mount. Four images of 1-µm-thick optical sections were gathered for each muscle, using a Zeiss LSM 510 Meta NLO system equipped to an Axiovert 200 M microscope. Images were acquired using Axiovision software (Carl Zeiss).

Statistical analysis

All values are presented as mean ± SD. Student's *t* test was used to compare differences between WT and mdx samples. A Kolmogorov–Smirnov test was used to compare the distribution of myotube nuclear numbers in mdx and WT cell culture, and to compare the distribution of LAMP1 level per myotubes in WT, mdx, scrambled PMO, and PMO Ex23-treated mdx myotubes. Chi-squared test was performed to determine the differences in proportions of cup-shaped and non-cup-shaped vesicle types between WT and mdx samples. Differences were considered to be statistically different at *p* < 0.05.

Results

Mdx myotubes are atrophic: a reduced cellular protein and RNA content when normalized to DNA quantity

At day 6 of differentiation, mdx and WT H-2K cells have the same myogenic potency as signified by the similarity of their fusion indices (91.16 ± 1.76 and 89.24 ± 2.59 , respectively), but mdx myotubes are smaller and contain fewer nuclei per myotube (Fig. 1a, c). Myotube protein amount per DNA was significantly lower in mdx than in WT myotubes (Fig. 1b). The red:green fluorescence of acridine orange, a measure of the ratio of RNA:nuclear DNA, indicated three-fold less RNA per nucleus in mdx than in WT myotubes (Fig. 1c, d).

Proteins are secreted preferentially from mdx myotubes in vitro

In order to compare the secretome profiles of WT and mdx myotubes, we used a quantitative proteomic approach

involving stable isotope labeling by amino acid in cell culture (SILAC) [29]. During 24 h of culture in conditioned media, mdx myotubes released about 0.5 % of their total protein content into the culture medium, and WT about 0.2 % (Fig. 2a). Some 267 proteins were identified in both the forward and reverse SILAC experiments as being released differentially between mdx and WT myotubes, of which 234 were released in excess by mdx myotubes (Fig. 2b, Suppl. Table 1).

We sorted the proteins according to DAVID subcellular localization attributions and found that most of the secreted proteins were cytosolic (231 of 267). The majority (228 of 267) were found at their normal intact molecular weight on SDS-PAGE gels. We could not detect a difference in cell death between mdx and WT myotubes in our culture conditions (see Suppl. Fig. 1).

Only 36 were classically described as being secreted or belonging to the interstitial extracellular matrix or membrane. Most of these (33 of 36) were over-secreted by mdx myotubes. These included fibronectin of normal molecular weight, suggesting a mechanistic link by which mdx myotubes could participate to the stimulation of fibrotic deposition.

Proteins released into the culture medium do not reflect passive membrane leakage

Our observation that most released proteins were full length prompted us to test whether their loss could be due to passive leakage through the membrane. In a series of tests, we found no evidence of such a generalized leakiness. Neither propidium iodide (6.68 kDa) (Suppl. Fig. 2a) nor Evans Blue (9.6 kDa, ~70 kDa when bound to albumin. Suppl. Fig. 2b) penetrated cells of either genotype. Similarly low penetration was observed for fluorescent dextrans of various molecular weights (Suppl. Fig. 3). The smallest dextran (3 kDa) was visible within a proportion (8–19 %) of myotubes after 5 min, with no difference in frequency or intensity of staining between mdx and WT. With dextrans of 10 or 40 kDa only, rare sporadic dextran-positive myotubes were observed after 5 min, mainly among WT (Suppl. Table 2). These data suggest that mdx myotubes are not intrinsically more permeable to large molecules than WT.

Aberrant vesicle trafficking in mdx myotubes

Cluster-based protein functional analysis of over-secreted proteins using DAVID (Suppl. Table 3) revealed clusters of proteins related to vesicles (cluster #3, enrichment score: 11.23) and vesicle trafficking (clusters #4, 5, 10, and 11, enrichment scores 9.92, 8.58, 4.28, and 4.19, respectively). In these protein clusters, several lysosomal markers, such as lysosome-associated membrane proteins 1 and 2 (LAMP1

results). Protein names are indicated on the y-axis with associated annotation terms on the x-axis. *Green squares* indicate that a particular protein belongs to that annotation category; *black squares* indicate that it does not

and LAMP2), cathepsin B and D were conspicuous (Fig. 3). The quantity of acidic organelles was significantly greater in mdx myotubes (Fig. 4a), suggesting a higher lysosomal activity. Immunostaining revealed intracellular LAMP1 vesicles at a much greater frequency in mdx than in WT myotubes (Fig. 4b). Similarly, in vivo we observed a conspicuous accumulation of LAMP1 at the sarcolemma (Fig. 4c) of myofibers in mdx mice aged 16 days but not in WT mice of this age.

Electron microscopy revealed two distinct morphologies of membrane vesicle to be secreted by WT and mdx myotubes: classical exosome cup-shaped vesicles, and another clearer and smoother (“non-cup-shaped”) morphology (Fig. 5a). These two types had a similar range of sizes, but the average size of the non-cup-shaped morphology was smaller (Fig. 5b). These non-cup-shaped vesicles made up a significantly greater proportion of the two vesicle types in mdx samples—60 %, compared to 34 % in WT (Chi-squared $p < 0.0001$; Fig. 5c)—and their average size was slightly smaller in the mdx. These vesicles

were obtained from filtered medium ultracentrifugated at $100,000 \times g$, but we also characterized heavier, larger material on EM, by ultracentrifugation at $20,000 \times g$ and omitting filtration: in this way shedding vesicles were identified to be secreted from WT and mdx, but no morphological differences were noted. Both WT and mdx vesicles expressed exosomal markers Tsg101 and LAMP1, whereas CD45, a marker of shedding vesicles, was faintly detected in WT vesicles (Fig. 5d).

LAMP1-vesicles contain MLCs, cytoskeletal proteins that are over-secreted by mdx myotubes

To check whether intracellular and secreted LAMP1 was colocalized in vesicles with over-secreted protein, we chose to focus on skeletal muscle-specific cytoskeletal proteins (Suppl Table 1). From the antibodies available at the Developmental Studies Hybridoma banks, we identified anti-myosin light chain 1–3 (MLC1–3, F310) as giving satisfactory results by Western blot on cellular (myotubes)

and secretory (conditioned culture medium) samples (Suppl Fig. 4a, b). The MLC1-3 antibody recognizes both Myosin Light Chains 1 and 3. An additional reason for choosing MLC1-3 as a representative of the over-secreted proteins was that we detected it at increased levels in the serum of pre-symptomatic 16-day-old mdx mice (Suppl Fig. 4c). The excess of myosin light chains in the serum of these mice is not attributable to myonecrosis since this does not occur until 20 days of age [30], and thus appears to reflect the findings in tissue culture. In this respect, it is distinct from muscle creatine kinase, which is barely detectable prior to the onset of myonecrosis [31, 32].

We delivered fluorescently tagged LAMP1 to mdx myotubes by cDNA transfection, and observed it to be colocalized with immunostained MLC1 in intracellular vesicles (Fig. 6a).

To detect secreted vesicles, we used sucrose gradient ultracentrifugation to fractionate the culture media of WT and mdx myotubes according to density (Fig. 6b). Vesicles were detected in the medium of both WT and mdx myotubes. In the WT, vesicles were restricted to densities of $\sim 1.18 \text{ g cm}^{-3}$, a range at which they have been identified previously [28, 33], while those from mdx myotubes were

present at this and several aberrant densities (~ 1.03 , ~ 1.05 , and $\sim 1.09 \text{ g cm}^{-3}$). Western blots of the isolated vesicle fractions showed the presence of MLC1-3 together with LAMP1 (Fig. 6b) in mdx culture medium-MLC1-3 were detected at only the intact molecular weight, 21.1 kDa, in the WT, but at two additional molecular weights in the mdx, one faint band at the approximate weight of MLC3 (17 kDa) and one strong band at a smaller molecular weight ($\sim 15 \text{ kDa}$), perhaps corresponding to a degradation product. These data demonstrate aberrant vesicle secretion by mdx myotubes, and vesicle-mediated secretion of MLC1-3, together suggesting a dysregulation of vesicle trafficking as a mechanism underlying the over-secretion of proteins from mdx myotubes.

Restoration of dystrophin expression rescues the secretome profile

To test whether we could reverse the secretome profile, we treated mdx myotubes with an exon skipping oligonucleotide, PMO Ex23, which restores open reading frame to the mutant mRNA. This treatment rescued the dystrophin level to about 30 % of the control WT value (Fig. 7a), and we

In both WT and mdx samples, the

non-cup-shaped vesicles are significantly smaller than the exosomes. Average non-cup-shaped mdx vesicle size was slightly smaller than WT. Box-plots show means with upper and lower quartiles. * $p < 0.05$, *** $p < 0.0001$. **c** Mdx samples had a significantly higher proportion of non-cup-shaped vesicles (Chi-squared test $p < 0.0001$). **d** Vesicles express exosomal markers. Western blot showing WT and mdx vesicle expression of Tsg101 and LAMP1 exosomal markers. CD45, a shedding vesicle marker, was faintly detected in WT samples

observed a concomitant decrease in secretion of proteins into the culture medium from 0.58 ± 0.01 % for mdx myotubes treated with an scrambled PMO control ("scrambled-PMO-treated"), to 0.48 ± 0.01 % for PMO Ex23-treated myotubes ($p = 0.005$). Much of this decrease comprised a partial restoration of the secretome profile towards the WT pattern, with 235 proteins secreted in excess (i.e., a ratio above 1) by scrambled-PMO-treated mdx myotubes compared with those treated with PMO Ex23 (Fig. 7b and Suppl Table 4): including a significant reduction in secretion of proteins recognized as being classically secreted or belonging to the interstitial extracellular matrix or membrane and, notably, a major drop in secretion of myosin light chain 1–3 (Fig. 7b inset panel).

The two comparisons: (1) mdx versus WT and (2) scrambled-PMO-treated mdx vs. PMO Ex23-treated mdx,

shared 84 proteins that were detected in both experiments. Of these, 53 (63 %) were rescued when treated with PMO Ex23. Application of a cut-off of 1.3-fold changes to the comparison of PMO Ex23-treated versus scrambled-PMO-treated mdx myotubes excluded proteins for which the two comparisons showed different directions of change arising from minor differences. This left 39 proteins, of which 36 were over-secreted in both comparisons—i.e., 36 of these proteins (92 %) were rescued in cultures where dystrophin expression was induced using PMO Ex23. We also observed a diminution of LAMP1 expression in the PMO Ex23-treated mdx myotubes as shown in cumulative rank plots (Fig. 7c). A two sample Kolmogorov–Smirnov test confirmed the visual impression that the LAMP1 content of mdx myotubes and of mdx myotubes treated with scrambled-sequence PMO showed consistently high LAMP1 content and did not

differ significantly from one another ($p = 0.114$) but that both differed from PMO Ex23 ($p < 0.0001$) which, in turn, differed from WT ($p = 0.001$). These data show that the aberrant vesicle trafficking observed in mdx myotubes is a direct consequence of the lack of dystrophin.

Discussion

Leakage of high molecular weight proteins such as the muscle isoforms of creatine kinase and pyruvate kinase into the serum has long been employed in the diagnosis of myonecrotic conditions, notably Duchenne muscular dystrophy [34–36] and is replicated in the murine mdx dystrophy. In the mdx mouse, the massive rise in serum levels of creatine kinase is synchronous with the onset of histologically observable myonecrosis at 3 weeks of age [31, 32], supporting the idea that this phenomenon arises from membrane disruption associated with necrotic damage to the muscle fiber. In the present study, we provide an array of evidence that traumatic leakage is not the only mechanism of egress of large molecules from muscle fibers but that skeletal muscle is also a secretory tissue and that the mechanisms of secretion are profoundly disturbed in muscle lacking the protein dystrophin. Our data strongly suggest that the excess of protein export from mdx myotubes is related to a disturbance of vesicular secretion, signifying a link between dystrophin and the regulation of vesicle trafficking.

Mechanism of protein export

Recent studies on C2C12 myoblasts have established the secretory profile of the myotube during differentiation [16, 17], and the SILAC analysis presented here assays differential levels of proteins commonly secreted by both wild-type and mdx myotubes at a late stage of differentiation. An understanding of the mechanisms involved in the increased export of proteins from mdx myotubes should reveal previously unsuspected features of the functional changes wrought within the muscle fiber by the lack of dystrophin.

A trivial explanation of our secretion findings would be that myotubes of mdx genotype are more sensitive than WT, dystrophin-expressing, myotubes to the stress conditions of tissue culture so that more of them die, or develop surface lesions and release their contents into the medium. Our analysis of the diminution of nuclear counts during the period of SILAC-analyzed protein secretion showed that loss of cells occurred in both WT and mdx cultures, but at indistinguishable rates. We had anticipated that mdx might be more sensitive than WT myotubes to the extra trauma of transfer to conditioned media on day 5 but, by all of our tests, either the converse was true or there was no difference; caspase 9 activity and nuclear loss were indistinguishable

between the two cell lines, and PARP1 cleavage was slightly less in mdx myotubes, suggesting that much of the necrosis-inducing cell damage derives from the mechanical and physiological challenges experienced *in vivo*. Certainly, our data conspire to the view that the greater protein release from mdx than WT myotubes is not attributable to at any detectable difference in lethal or sub-lethal cellular stress in our tissue culture system. Nor did we find any evidence that mdx myotubes are intrinsically more leaky than WT, for we found no significant penetration of propidium iodide, Evans Blue Dye or a range of sizes of fluorescent dextrans. Both WT and mdx myotubes permitted entry of 3 kDa dextran but neither were penetrated by the 10 or 40 kDa reagents and in no case did the marker penetrate mdx myotubes to a greater extent than WT myotubes. These findings, together with the fact that a majority of intracellular proteins did not follow the trend of excess release into the culture medium of mdx myotubes, led us to consider other, specific, mechanisms of protein export, such as the microvesicle pathways.

Analysis of the secretome of mdx myotubes revealed clusters of proteins involved in vesicle trafficking (see “Results”) and secreted vesicles were identified in the conditioned media of both WT and mdx myotubes, but in excess and at aberrant densities in the mdx. Secreted vesicle fractions of all densities in the mdx cell line contained both the vesicle marker LAMP1 and secreted myosin light chain. LAMP1 is known for its role in autolysosome function but, recently, has been implicated in a non-conventional secretion pathway [37, 38]. Colocalization of LAMP1 with MLC was also observed within the cultured mdx myotubes (Fig. 6b), where conspicuous accumulations of LAMP1 +ve structures far exceeded those in WT myotubes (Fig. 4b). Similarly, *in vivo* LAMP1 +ve structures were readily demonstrated within pre-necrotic mdx TA muscle of 16 day mice, but barely detectable within those of age-matched WT mice (Fig. 4c). These data suggest that the underlying disturbance is a dysregulation of the constitutive function of vesicle trafficking rather than a catastrophic breakdown of intracellular regulation of the type seen in myonecrotic lesions *in vivo*. This aberrant vesicle trafficking is firmly tied to the absence of dystrophin by the PMO Ex23 induced reversal of the secretome profile, the decrease in vesicle markers and reduction in the quantity of LAMP1-positive vesicles in mdx myotubes (Fig. 7). It is noteworthy in this respect that dystrophin has been detected in lysosomal membranes in vacuolar myopathies caused by LAMP2 deficiency [39–41] and in colchicine induced myopathy [42], both characterized by accumulation within myofibers of dystrophin positive vacuoles. In addition, expression of Niemann-Pick C1 (NPC1) protein—that is localized in late endosome/lysosome membranes—is reported to ameliorate the mdx phenotype, with a dramatic decrease in creatine kinase blood level and in central nucleation [43]. Together with the present data, these

findings suggest a link- direct or indirect- between dystrophin and the function of lysosomal vesicles.

The relevance of these vesicle-associated mechanisms to DMD is supported by observations by Konagaya et al. [44] of traces of myosin light chain 3 in the serum of normal subjects and much greater concentrations in Duchenne patients. While they, quite reasonably, interpreted this as leakage associated with myonecrosis, our evidence of release of MLC1-3 into the blood plasma as well as the accumulation of LAMP1-positive vesicles at the sarcolemma of muscle fibers of young, pre-myonecrotic, mice suggests that, even in the absence of any overt signs of pathology, dystrophin-deficient muscle fibers are prone to vesicle-mediated export of this protein. Secreted vesicles of various sizes and origins have been observed in tumor cells, endothelial cells, and immune response cells [45–48]. These structures transport functional proteins and RNA and have been postulated to play a role in intercellular communication in inflammatory cells [48]. Proteins found inside vesicles do not belong to any particular cell compartment or functional family and represent about 7.5 % of the entire Uniprot database, suggesting that they may serve some jettisoning function, an idea supported by the detection of microvesicles in the blood [49]. In the context of dystrophin-deficient myotubes which are held to be susceptible to cellular stress [50–53], one might expect accumulation of misfolded or damaged proteins, as observed in neurodegenerative diseases [54] or during ageing [55] which, classically, are thought to be eliminated through the proteasomal or autophagic pathways [56]. Indeed, in dystrophin-deficient muscles, these pathways are activated together with the ubiquitous calpain systems [14, 57–59]. However, most of the proteins found in our SILAC analysis were not degraded, although they may have been misfolded or non-functional; whatever the case, they had clearly eluded the classical degradation pathways. The vesicle-mediated release we observe resembles the system described in yeast whereby full length proteins are released from the autophagosome by direct fusion with the plasma membrane rather than with the degradation vacuole [60]. On the other hand, several of the proteins over-secreted by mdx myotubes are active signaling molecules that would signify some paracrine activity associated with these vesicles. And, given the large mass of skeletal muscle, chronic disturbance of the pattern of vesicle secretion by intact dystrophinless muscle fibers is likely to exert widespread effects on muscle and other tissues in the dystrophic individual.

Dystrophin-deficiency leads to myotube atrophy and a disruption of metabolism

Although not foreseen, it emerged that the dystrophin-deficient myotubes were atrophic by several criteria; they

contained fewer nuclei per fiber, less RNA per nucleus and less protein per DNA, despite which, they were exporting more protein per myotube than WT. Interestingly, the low numbers of nuclei per mdx myotube occurred in the context of identical overall fusion indices in mdx and WT cultures, suggesting that it is not attributable to an intrinsic fusion deficiency of the mdx myoblasts but, rather, indicates a difference in intercellular signaling. A candidate that springs to mind is IL4, which has been implicated in the regulation of numbers of nuclei per myofiber [61]. SILAC analysis is insufficiently sensitive to detect differences in production of low-abundance cytokines, so the linkage between these general metabolic disturbances and the excessive export of proteins from mdx myotubes into the culture medium awaits further investigation.

In vivo, adult mdx mice have larger muscles than wild-types [31]. Likewise there are greater amounts of protein in mdx muscles aged 50–200 days than in age-matched wild-types, and greater proteasome activity implying more protein turn-over in mdx muscle [62]. The drive to synthesis of myofibrillar proteins switches gear, abruptly, at 3 weeks of age, when growth by increase in myonuclear number ceases and is replaced almost entirely by increase of myonuclear domain [63]. It may not be coincidental that the phase of florid myonecrosis in vivo is unleashed at the time of this transition [64]. In tissue culture, where there is no drive to work-associated growth, mdx myotubes are at least as resilient as WT myotubes; physical and physiological stresses are insufficient to trigger differential cell damage and there is no overt myonecrotic pathology. Thus, while evidence linking in vivo with in vitro mechanisms is necessarily circumstantial, we note that cultured myotubes are closely comparable with the immature postnatal muscles in vivo; these do not degenerate and do not release massive amounts of creatine kinase into the serum until around 3 weeks of age. In related in vivo work we have discerned a $21.68\% \pm 1.14$ lower ratio of F-actin per myonucleus in myofibers extracted from 1 to 2-week-old mdx as compared with age-matched WT mice ($n = 4$), suggesting that mdx muscle fibers in vivo are atrophic prior to the onset of pathological symptoms at 3 weeks of age.

One might speculate whether the lower protein content per myotube in mdx than WT cultures is a reflection of the greater protein export but the other differences, the lower myonuclear numbers, reduced RNA per nucleus, and the reduction in a number of proteins involved in protein synthesis, argue against this simple explanation. Certainly, reactive oxygen species (ROS) production are suggested as a primary feature of dystrophinopathies. In vitro, dystrophin-deficient myotubes are more susceptible to ROS damage [65], while, in vivo, there is evidence of oxidative stress such as lipid oxidation [66], and greater amounts of oxidized proteins in mdx mice [67] and in DMD patients [68].

The two suggested main sources of ROS production are the mitochondria and the NADPH oxidase [53]. In vivo, mdx muscles show an accumulation of swelling mitochondria [69–71] and a lower mitochondrial respiration capacity. Our secretome analysis of mdx myotubes suggests some dysfunctions of the mitochondria, as there is an over-secretion of mitochondrial markers in mdx myotubes (Suppl Table 1). Increased ROS production may exert deleterious effects on the contractile machinery, as suggested by [72], and this may partly explain myotube atrophy.

Conclusions

Our findings suggest a new layer of pathological processes in the progression of the mdx dystrophy and, by extension, in DMD. The standard view is that the primary pathological defect arising from lack of dystrophin enfeebls the muscle fiber membrane and precipitates myonecrotic lesions which, in turn, drive satellite cells towards a state of exhaustion and, at the same time, activate inflammatory and fibrogenic mechanisms. We hypothesize that this pathological cascade is preceded by, and subsequently accompanied by a more generalized excess export of specific proteins, the overall pathological consequences of which merit further investigation. Even if the abnormal export of proteins is not, in itself, so acutely disruptive as the myonecrotic lesions, such lesions are extant in only a minority of the muscle bulk at any given moment and the cumulative effect of increased protein export from the major mass of intact muscle may be a significant factor in driving pathological change. This would certainly fit with the observation that the buildup of fibro-fatty tissue in mdx mouse muscles occurs predominantly during the second year of life when the mdx myopathy is considered to be relatively quiescent in the limb muscles [73]. At present, it is the overtly myonecrotic features of DMD that catch our attention as potential therapeutic targets but the more generalized chronic leakage of proteins from apparently intact myofibers, which constitute the bulk of the muscle for most of the time, may prove to be equally deserving of attention in this respect.

Acknowledgments We would like to thank Douglas Johnson for his help with preliminary SILAC experiments, Dr. Toshifumi Yokota, Dr. Qi Lu, Dr. Jyoti Jaiswal and Dr. Kanneboyina Nagaraju for useful discussion and technical advice. This work was supported by IDDRC 1P30HD040677 and NCMRR 2R24HD050846 NIH grants and by funding from the Foundation to Eradicate Duchenne and from Wellstone Center, U54HD053177, W81XWH-05-1-0616, and by the ANR Genopath IN-A-FIB and the AFM (Association Française contre les Myopathies). The monoclonal antibodies F310 and S21 developed by Dr. Stockdale F.E. [Developmental Studies Hybridoma Bank (DSHB)] were developed under the auspices of the NICHD and maintained by The University of Iowa, Department of Biology, Iowa City, IA 52242.
